1 Executive Summary

Sediment characteristics and populations and communities of the monitored macrofaunal taxa have not changed markedly at the intertidal or subtidal sites over the past two years of monitoring. The intertidal communities at Hamilton Landing, Te Kapa Inlet and Cowans Bay have continued to become more similar to each other, as have those of Jamieson Bay and Mid Harbour. The subtidal communities of Sites A and C are also currently very similar.

A total of 33 intertidal populations are currently showing trends in abundance; approximately half of these are increasing trends and half are decreasing trends. All sites have populations that are exhibiting ecologically significant trends; most occur at Hamilton Landing and Te Kapa Inlet, and the least at Mid Harbour. Seven subtidal populations are exhibiting trends in abundance. Six of these are increases in abundance of taxa known to prefer medium amounts of mud.

Of most concern is that four species considered sensitive to increased suspended sediment concentrations are exhibiting declines in abundance at the intertidal sites (Table 10). Two ecologically important bivalve species, *Macomona liliana* and *Austrovenus stutchburyi*, and the polychaete *Scoloplos cylindrifera* continue to decline in abundance at the muddiest site, Hamilton Landing. *Macomona* is also declining at Jamieson Bay. Decreasing trends were detected for *Austrovenus* and the nut shell, *Nucula hartvigiana*, at Te Kapa Inlet. These declines are likely to be correlated with the continued expansion of the muddy portion of the Te Kapa Inlet site noted over the monitored period.

The decreases noted in the *Macomona* populations at Mid Harbour and Te Kapa Inlet in previous years are no longer apparent with two more years of data due to significant recruitment events. Mid Harbour contains reasonable numbers of spawning sized individuals, indicating that this increase may continue in future years as these resident adults continue to reproduce. Abundances of spawning sized individuals are low at Te Kapa Inlet however, and recruitment at this site relies on transport of juveniles from elsewhere in the harbour.

Very few of the intertidal populations exhibit highly predictable cyclic abundance patterns, where peaks in abundance occur in the same monitoring month every year.

Numbers and sizes of *Atrina zealandica* are similar at both of the subtidal sites. Numbers are low and the sizes of *Atrina* have not increased much over the past two years, probably reflecting the fact that the growth of these populations is slowing as the individuals age and reach their maximum size..

An additional intertidal monitoring site was established at Dyers Creek in October 2005. The Dyers Creek subcatchment is one of the priority subcatchments being targeted for remedial work under the Mahurangi Action Plan. Monitoring at this site was implemented in response to this, in order that any changes over time in its ecology may be able to be linked to these changes in catchment management. Comments on trends and patterns in abundance of the monitored populations and community at this site will be made in future reports.

This monitoring programme has continued to provide very useful information on trends and cycles in monitored taxa populations and sediment characteristics that can be used to guide and monitor the effectiveness of catchment management within Mahurangi Estuary. With two more years of data our previous recommendations concerning the need to investigate and implement improved sediment controls still apply, as we are still detecting declines in abundance of taxa known to be sensitive to increased sediment loading. Recent evidence of recruitment of juvenile bivalve populations is encouraging, and highlights the potential for the recovery of some areas of the harbour should sediment control measures be effective.

2 Introduction

In July 1994 a long-term ecological monitoring programme of Mahurangi Estuary's intertidal and subtidal benthic communities was started. The monitoring programme was designed to:

- ❑ provide stocktaking of resources under stewardship;
- ❑ provide information on the ecology of the intertidal and subtidal benthic communities for the Mahurangi Estuary Management Plan (Mahurangi Action Plan, MAP);
- ❑ assess the overall condition of Mahurangi Estuary in terms of its benthic communities; and
- ❑ provide a basis on which to document any ecological changes that may occur as a result of catchment and estuary development.

Specific sites and populations (Appendix 1) for this long-term monitoring programme were identified from a survey conducted in 1993, and recommended in a previous report to ARC Environment (Cummings et al. 1994).

This monitoring programme has now been running for 12.5 years. In this report, we comment on the temporal variation in abundance of some monitored macrofaunal populations at the intertidal and subtidal sites, and on the temporal variation in abundance and size of the horse mussel, *Atrina zelandica*, at the subtidal sites. On the basis of trend and community analyses of the monitored taxa, we describe the current ecological status of the harbour and make recommendations for the future of this monitoring programme.

3 Methods

3.1 Intertidal Sites

In July 2004, five permanent intertidal sites were established in locations predetermined from an initial survey of the estuary conducted in April 1993 (Cummings et al. 1994; Figure 1). Four of the five sites cover areas of 9000 m² and are situated at about mid-tide level. The fifth intertidal site (Jamieson Bay) is constrained by the size of the bay and occupies a slightly smaller area (7200 m²). This latter site also covers a greater tidal range than the other sites due to the steep gradient of the beach.

In October 2005, an additional permanent intertidal site was established at Dyers Creek. The site was chosen and established by the ARC, in the approximate vicinity of the site initially surveyed by NIWA in 1993 (Cummings et al. 1994).

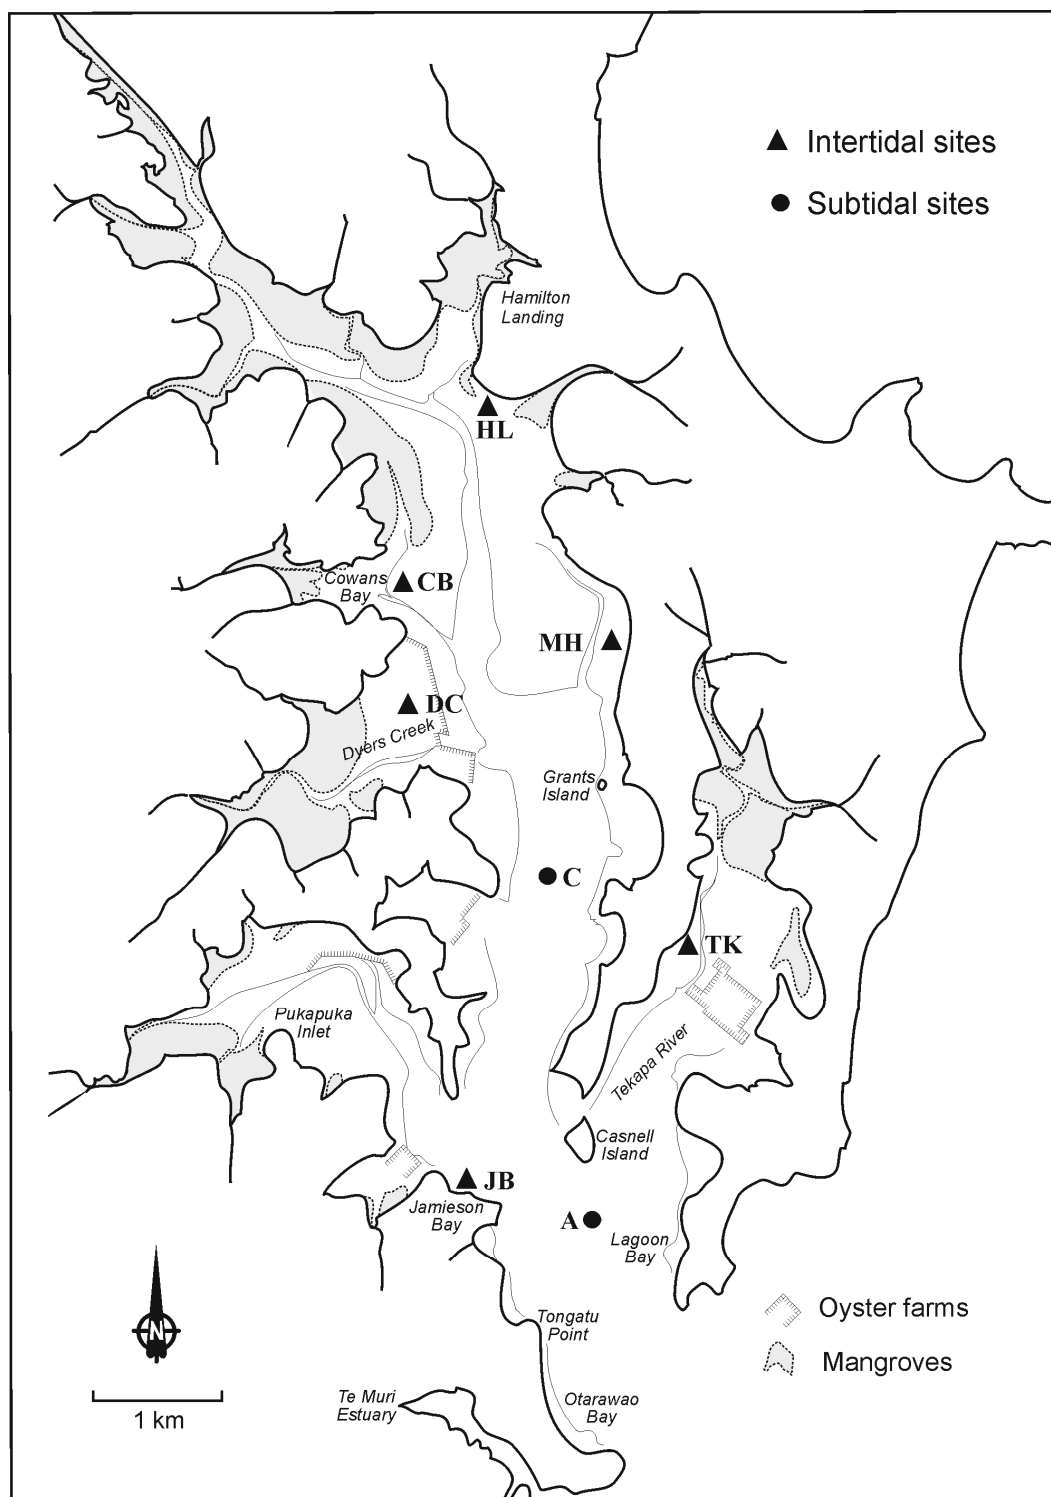

All six intertidal sites are sampled at three-monthly intervals.

3.1.1 Macrofauna

On each sampling occasion, core samples (13 cm diameter, 15 cm deep) are collected at 12 predetermined locations at each site. To provide adequate dispersion over the site, each site is 'divided' into 12 equal blocks and one core sample taken from a random location within each block. To reduce the influence of previous sampling activity and spatial autocorrelation (Hewitt et al. 1994; Pridmore et al. 1990; Thrush et al. 1988, 1994), samples are not positioned within a 5 m radius of each other or of any samples collected in the previous 12 months. Core samples are sieved (500 µm mesh) and the residues stained with rose bengal and preserved in 70% isopropyl alcohol in seawater. Samples are then sorted, identified to the lowest possible/practical taxonomic level, counted and stored in 50% isopropyl alcohol. Following the recommendations of an earlier report (Cummings et al. 1997), the monitored bivalve species are now measured on each sampling date, to enable determination of the number of individuals in different size classes (i.e., ≤ 4 mm, ≥ 4 –8 mm, ≥ 8 –16 mm, ≥ 16 mm). Measurements are made using either electronic callipers, or a camera lucida and digitising pad.

Figure 1.

Map of Mahurangi Harbour, showing locations of the intertidal and subtidal monitoring sites. Intertidal site abbreviations are as follows: CB = Cowans Bay; DC = Dyers Creek; HL = Hamilton Landing; JB = Jamieson Bay; MH = Mid harbour; TK = Te Kapa Inlet.

3.1.2 Sediment characteristics

Sediment samples for grain size analysis were collected from each site in April of each year up to April 2000. Since July 2000, sediment samples have been collected on each sampling occasion (following the recommendations made by Hewitt 2000). Surface sediment (0 - 2 cm) is collected adjacent to every second macrofauna core sample at each site and bulked for subsequent analysis. Prior to analysis, the samples are homogenised and a subsample taken. They are then digested in 6% hydrogen peroxide until all organic matter is removed, and sampled by wet sieving and pipette analysis (Gatehouse 1971). The April 1996 samples were analysed using a Mastersizer Laser Analyser (see Cummings et al. 1999). The results of the grain size analyses are presented as percentage composition of gravel/shell hash (>2000 µm), coarse sand (500 – 2000 µm), medium sand (250 – 500 µm), fine sand (62.5 – 500 µm), silt (3.9 – 62.5 µm) and clay (<3.9 µm).

Also beginning in July 2000, the organic content and chlorophyll *a* content of the sediments at each site have been assessed on each sampling occasion (as recommended by Hewitt 2000). To determine the organic content, 1 teaspoon of the homogenised sediment sample collected for grain size analysis is dried to constant weight at 60°C, and combusted for 5.5 h at 400°C. Six small sediment cores (2 cm diameter, 2 cm deep) are collected at each site to assess sediment chlorophyll *a* content. These sediment cores are collected adjacent to every second macrofaunal core sample, pooled and stored frozen and in the dark. The samples are freeze dried prior to analysis. Chlorophyll *a* is extracted by boiling this freeze dried sediment in 90% ethanol, and the extract processed using a spectrophotometer. An acidification step is used to separate degradation products from chlorophyll *a* (Sartory 1982).

At Te Kapa Inlet, most of the site is 'muddy', but a portion of it is relatively sandy. Therefore, sediment samples for the above analyses are collected from the two different areas of this site. These are referred to as 'Te Kapa Inlet mud' and 'Te Kapa Inlet sand', respectively.

3.2 Subtidal Sites

Three permanent subtidal sites were established in locations predetermined from the initial survey of the estuary (Cummings et al. 1994). Following the recommendations made in our 2001 report (Cummings et al. 2001), the number of subtidal sites routinely monitored was reduced, with Sites A and C continuing to be monitored. Both of these sites are situated adjacent to the main estuary channel, in approximately 6 - 10 m of water (Figure 1). A major reason for subtidal sampling in Mahurangi Estuary is to monitor the horse mussels (*Atrina zelandica*).

Due to the difficulties of working subtidally in Mahurangi (e.g., poor visibility, strong tidal currents), each site is relocated at the surface via visual line-of-sight bearings and a weight with a line attached is then dropped to the estuary floor. Thus, a haphazardly chosen 50 m² area is sampled within our approximately 300 m² site on each sampling occasion. All sampling is carried out by SCUBA divers.

Transects (20 - 50 m long) of the horse mussels and their associated fauna have been videotaped at each site on each sampling occasion. The video footage is taken from a target height of 40 cm above the seafloor, resulting in a transect width of approximately 50 cm. Information gained from the video supplements the quadrat data and provides a visual archive of the communities associated with the horse mussel beds.

Subtidal sites were sampled at six-monthly intervals, beginning in October 1994. Due to recommendations made in Cummings et al. (2001), since July 2001 subtidal sites A and C have been sampled every 3 months.

3.2.1 Macrofauna

On each sampling occasion, 12 core samples (10 cm diameter, 16 cm deep) are collected randomly within a 10 m radius of the weight dropped to the estuary floor. Samples are then processed as described for those from the intertidal sites (see above).

3.2.2 Sediment characteristics

As at the intertidal sites, surface sediment for grain size analysis has been collected from each site in April of each year up to April 2000, and on every sampling occasion thereafter. In addition, beginning in July 2000, sediments at each site are now also assessed for organic and chlorophyll *a* content. Collection and analyses of these sediments are as described for the intertidal sites (see above).

3.2.3 *Atrina zelandica*

Estimates of size and density of the *Atrina* are made at each subtidal site. Ten quadrats (0.25 m²) are haphazardly placed on the estuary floor and the number of *Atrina* contained in each quadrat is recorded. The size (maximum shell width) of five randomly selected live *Atrina* within each quadrat is also measured. During the October 1994 sampling, mean numbers of *Atrina* in the quadrats were derived from 8 and 15 quadrats at Sites A and C, respectively. Also during October 1994 sizes of *Atrina* were compiled from measurements of individuals along transects at Site A and adjacent to quadrats at Site C. A total of 32 and 21 *Atrina* were measured at Sites A and C, respectively, on this date.

On the April 1995 sampling occasion we noted that the majority of *Atrina* individuals at one of the sites were dead. Therefore, on every subsequent

sampling occasion the number of live and dead *Atrina* within each quadrat has been recorded, and only live individuals are measured. The number of live individuals on the previous sampling occasions was estimated from the video footage.

3.3 Analyses of macrofaunal abundance

3.3.1 Biological interpretation of patterns

Plots of total abundance for each monitored population over the monitored period were visually examined to identify repeatable cyclic patterns that indicate seasonal or inter-annual variation in recruitment. We also consider the density of each species at each site in light of our knowledge of the natural history of each species, to ensure that our statistical analyses are interpreted in a biologically meaningful fashion.

3.3.2 Trend analysis

To formally identify any suggested trends in the abundance of the monitored taxa at both the intertidal and subtidal sites, trend analyses were conducted. Autocorrelation in each time series was investigated using chi-square probabilities (SAS/ETS). Where autocorrelation was indicated, increasing or decreasing trends were investigated by adjusting parameters and significance levels (AUTOREG procedure, SAS/ETS). Otherwise ordinary least squares regression was carried out. Only linear trends were investigated as investigation of residual variability suggested no other responses. Analyses were carried out on both the original time series and the baseline population (i.e., when peak abundances occurred in a repeatable, cyclic pattern, they were removed, and the remaining 'basal' population analysed). Doing both analyses enables identification of trends that are due to changes in recruitment which may not (yet) be affecting basal abundances, and thus aids biological interpretation.

3.3.3 Community analysis

To make an overall assessment of stability of sites over time, we constructed multivariate ordination plots using monitored taxa only. The intertidal and subtidal sites were analysed separately using correspondence analysis (CANOCO; ter Braak, 1986).

4 Results and Discussion

4.1 Intertidal sites

4.1.1 Sediment characteristics

The sediment grain size composition of the five original intertidal sites continues to contain a higher proportion of fine sand and lower amount of medium sand compared with the first two years of monitoring (Figure 2, Appendix 2). The Dyers Creek site sediments are also comprised predominantly of fine sand (79.48-90.25%), with some silt and clay (3.62-12.79 and 1.65-4.87%, respectively) (Figure 2, Appendix 2).

The organic and chlorophyll *a* content of the sediments at each site from July 2000 to January 2007 are provided in Appendix 3. The organic content is lowest at Dyers Creek (range 0.76-1.34% since monitoring began at this site in October 2005), and highest at Hamilton Landing (range 1.58-6.65%). While there is no predictable pattern in organic content over time that is consistent across all sites, there are similarities between Cowans Bay, Jamieson Bay and Te Kapa Inlet (Figure 3).

Chlorophyll *a* content of the sediments continues to be highest at Cowans Bay (10.66-23.08 $\mu\text{g g}^{-1}$ sediment) and lowest at Jamieson Bay (1.76 - 6.76 $\mu\text{g g}^{-1}$ sediment). Dyers Creek chlorophyll levels are intermediate between these sites (5.16-8.10 $\mu\text{g g}^{-1}$ sediment). There is no easily discernable temporal pattern in sediment chlorophyll *a* levels across the sites (Appendix 3). However, it is interesting to note that four of the sites have exhibited their highest ever chlorophyll *a* levels in July (i.e., Hamilton Landing, Jamieson Bay and Te Kapa Inlet (muddy region) in July 2001, Mid Harbour in July 2002; Appendix 3).

Figure 2.

Changes in the proportions of mud (i.e., silt/clay; $<63\ \mu\text{m}$), fine sand ($62.5 - 250\ \mu\text{m}$), medium sand ($250 - 500\ \mu\text{m}$) and coarse sediment ($>500\ \mu\text{m}$) content at each of the intertidal sites over the monitored period. Detailed sediment grain size data, on which these graphs are based, is presented in Appendix 2.

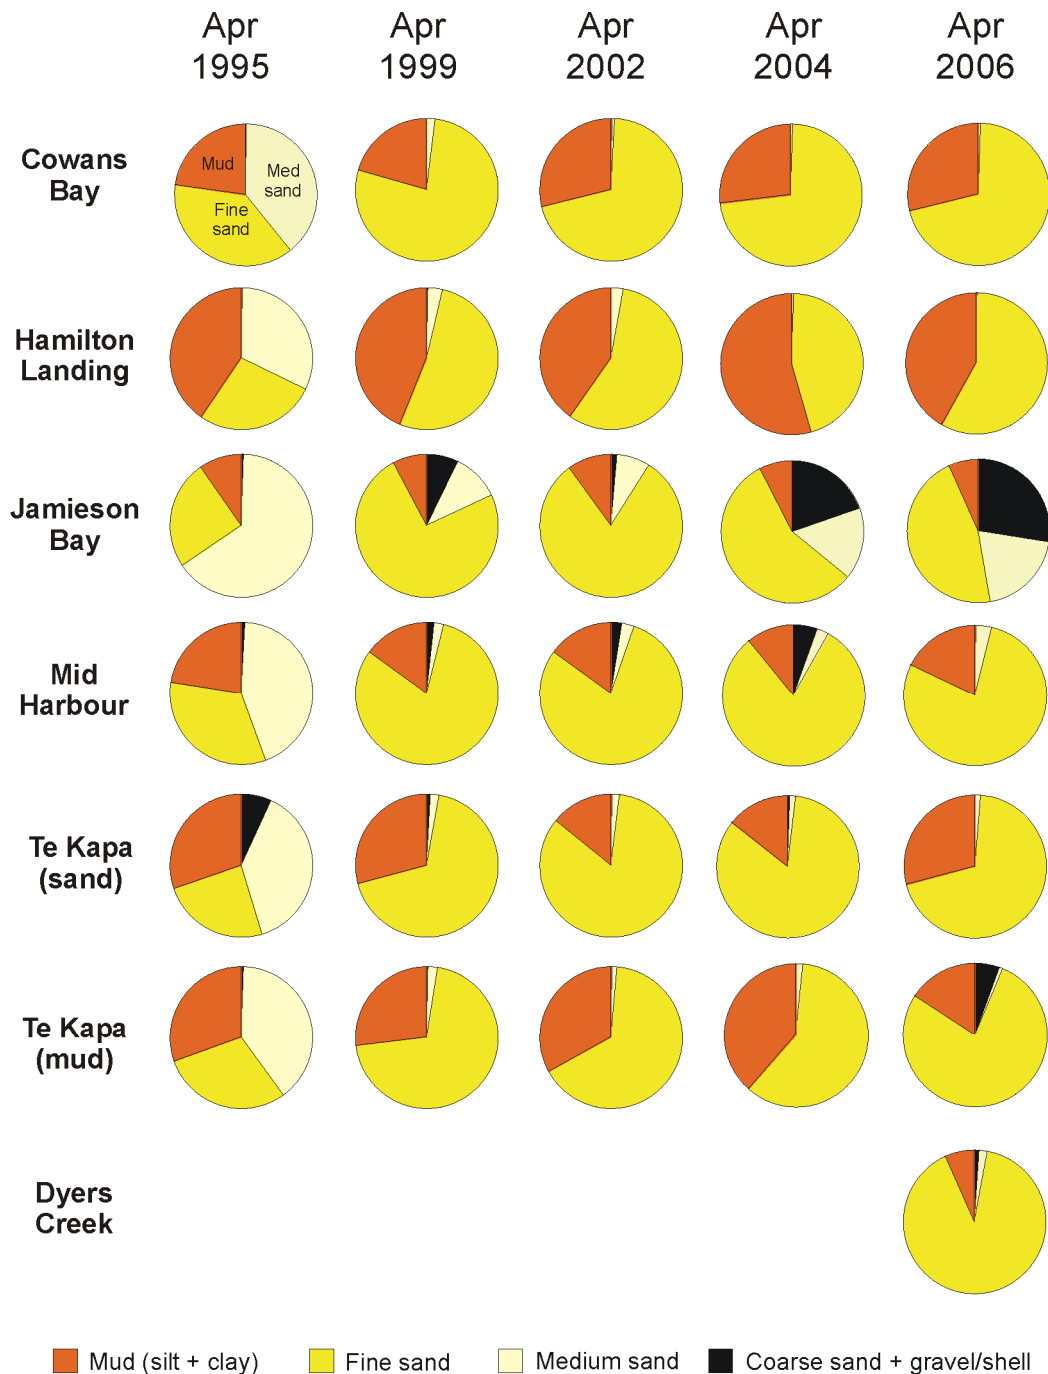

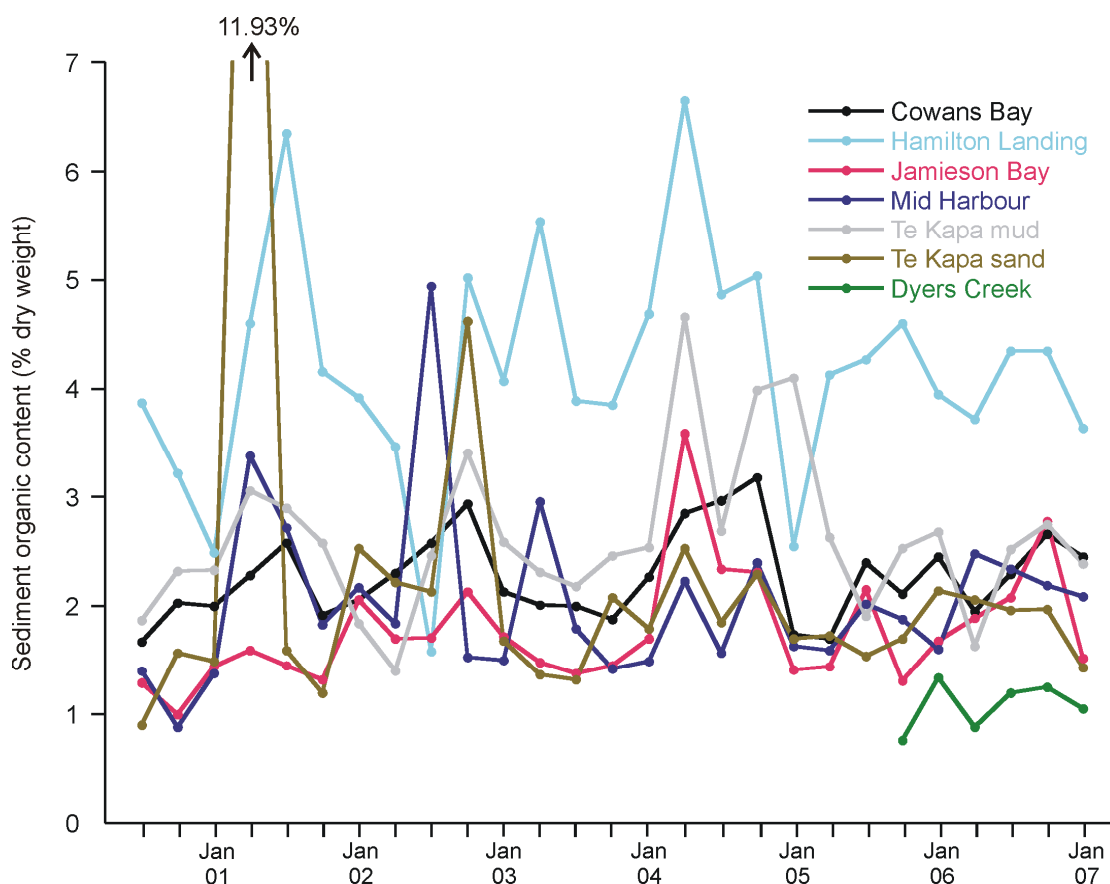

Figure 3.

Sediment organic content at the intertidal sites on each sampling occasion since July 2000.

4.1.2 Macrofauna - comments on the abundance of common taxa

Throughout this report 'total' abundances (i.e., total numbers of individuals collected in 12 samples) of the monitored taxa are discussed. The abundances of all the intertidal monitored taxa collected at each site on each sampling date since the last report (i.e., from April 2005 to January 2007) are given in Appendix 4¹.

The following are site-by-site descriptions of the monitored macrofauna. For each site, we discuss the three most abundant taxa, populations exhibiting visually identifiable cycles in abundance, and populations for which statistically identifiable trends in abundance have been detected by trend analysis. A table summarising the trend analysis results is given at the end of this section (Table 6).

¹ *Prionospio aucklandica* referred to in this report follows taxonomic change to *Aquilaspio aucklandica*.

4.1.2.1 Cowans Bay

The polychaete *Cossura* sp. has dominated this site on all but one occasion since monitoring began in July 1994 (Table 1), with 135 to 738 individuals found on each sampling date. The decline in abundance of *Arthritica bifurca* noted in our last report has not continued, and this small bivalve has featured amongst the dominant taxa on six of the eight most recent sampling dates. Polydorid polychaetes were the third most abundant monitored taxa in April 2005; they had not previously featured amongst the dominant taxa at this site (Table 1), and have not since. The polychaete *Heteromastus filiformis*, the amphipod *Torridoharpinia hurleyi*, and the nut shell *Nucula hartvigiana* (Figure 4) were also common over the past two years at Cowans Bay (Table 1).

Table 1.

The three dominant taxa collected at Cowans Bay from July 1994 to January 2007. The most abundant taxa are on the left hand side of the table.

Populations showing cyclic abundance patterns

Nucula hartvigiana exhibits peaks in abundance in January of most years, except for 2002 and 2003 when peaks occurred in October (Figure 4). Similarly, the mud crab *Macrophthalmus hirtipes* is most abundant in January or October (Figure 5). *Heteromastus filiformis* numbers generally peak in July or October, with smaller peaks noted in October 2006.

The apparent cyclic pattern in abundance noted for *Cossura* sp. in our last report is no longer apparent with two more years of data

Figure 4.

Total number of *Nucula hartvigiana* collected on each sampling occasion at Cowans Bay. Peaks in abundance occur annually, most often in January months, and an increasing trend in basal abundance of this bivalve was also detected.

Figure 5.

Total number of *Macrophthalmus hirtipes* collected on each sampling occasion at Cowans Bay. Peaks in abundance of this crab occur annually, most often in January or October months.

Populations showing trends in abundance

Four new trends in abundance were detected at Cowans Bay: the polychaetes *Cossura* sp. and *Prionospio aucklandica* and nemerteans, all of which exhibit decreasing trends, and an increase in abundance of the bivalve *Nucula hartvigiana* (Table 6). *Cossura* is found in very high numbers at this site, and there has been a slight decline in its peak abundances over the monitored period. However, these numbers have increased in recent months (195-405 individuals were found over the past two years) and it is likely this trend is just a reflection of fluctuations in abundance of this polychaete. The magnitude of the trend detected for *Prionospio* is very small (see Table 6); this polychaete has never been very abundant at this site (2-3 individuals on most occasions). A small decreasing trend was also detected for nemerteans, due to the smaller peak in abundance in recent years. This species has been found in low numbers at this site in recent years (<10 individuals).

An increase in baseline abundances of *Nucula hartvigiana* was detected, reflecting higher numbers of this bivalve since October 2000 (Figure 4); there was no trend in overall abundance (Table 6). While a statistically significant increasing trend in abundance was detected for *Paracalliope novizelandiae*, it was of very low magnitude (Table 6). This amphipod has been found on only two occasions at Cowans Bay over the past two years (when only 1 individual was collected on each date), and we do not place much emphasis on this trend.

The decline in polydorid polychaete abundances detected in past reports is now no longer apparent (Figure 6A). Abundances of this taxa over the past two years have been amongst the highest recorded over the monitored period. The unusually high numbers of *Torridoharpinia hurleyi* found in January 2005 (i.e., 312 individuals) have not persisted (Figure 7). Consequently, and as expected, the increasing trend in numbers of this amphipod detected in our 2005 report is no longer apparent (Table 6).

Figure 6.

Total number of polydorids collected on each sampling occasion at the intertidal sites. Peaks in abundance of this polychaete occur annually at Hamilton Landing and Jamiesons Bay, and approximately every two years at Te Kapa Inlet.

Decreasing trends in abundance were detected at all sites except Cowans Bay.

Figure 7.

Total number of *Torridoharpinia hurleyi* amphipods collected on each sampling occasion at Cowans Bay. The increasing trend in abundance detected for this taxa in our 2005 report is no longer apparent.

4.1.2.2 Hamilton Landing

Cossura sp. and *Heteromastus filiformis* are still the first and second most abundant of the monitored species at Hamilton Landing, and both continue to increase in abundance as the monitoring programme continues. *Cossura* recorded its highest ever numbers at this site in April 2006 (1234 individuals). In the past two years *Aridicea* sp., polydorids, oligochaetes and *Arthritica bifurca* have featured as the third most abundant monitored taxa at this site.

Populations showing cyclic abundance patterns

The small bivalve *Arthritica bifurca* exhibits a greater than annual cycle in its abundance, with peaks in January or October. (Figure 8).

Polydroid polychaetes have exhibited peaks in abundance in January most years, except for 1995 and 2002 when these occurred in October and April, respectively. Numbers of polydorids have been considerably lower in the last half of the monitored period (i.e., since October 1999), but remain steady (Figure 6B).

The crab *Macrophthalmus hirtipes* and the polychaete *Heteromastus filiformis* exhibit peaks in abundance every year, and most often in October (Figures 9 and 10).

Figure 8.

Total number of *Arthritica bifurca* collected on each sampling occasion at Hamilton Landing. Peaks in abundance of this bivalve occur on a greater than annual cycle, in January or October months.

Figure 9.

Figure 10.

Total number of *Heteromastus filiformis* collected on each sampling occasion at Hamilton Landing. Peaks in abundance of this polychaete occur annually, most often in October months. An increasing trend in overall and basal abundances was also detected.

Populations showing trends in abundance

Trends in abundance over the monitoring period were detected for 10 of the monitored populations at Hamilton Landing; all of these were also noted in our last report (Table 6). Five populations exhibit increases in abundance, and five exhibit decreases.

Cossura sp. and *Heteromastus filiformis* (Figure 10) both exhibit strong increasing trends, and for the latter this is also apparent in basal abundances (see Table 6). Abundances of *Heteromastus* in the past two years have been lower than previously, and may indicate a tailing off of this increase (Figure 10). Smaller increases in abundance were detected for *Aricidea* sp., *Prionospio aucklandica* and nemerteans (Table 6).

Overall and baseline abundances of polydorids have declined over the monitored period (Table 6). As noted above, its numbers have been relatively low, but steady, at this site since October 1999 (Figure 6B).

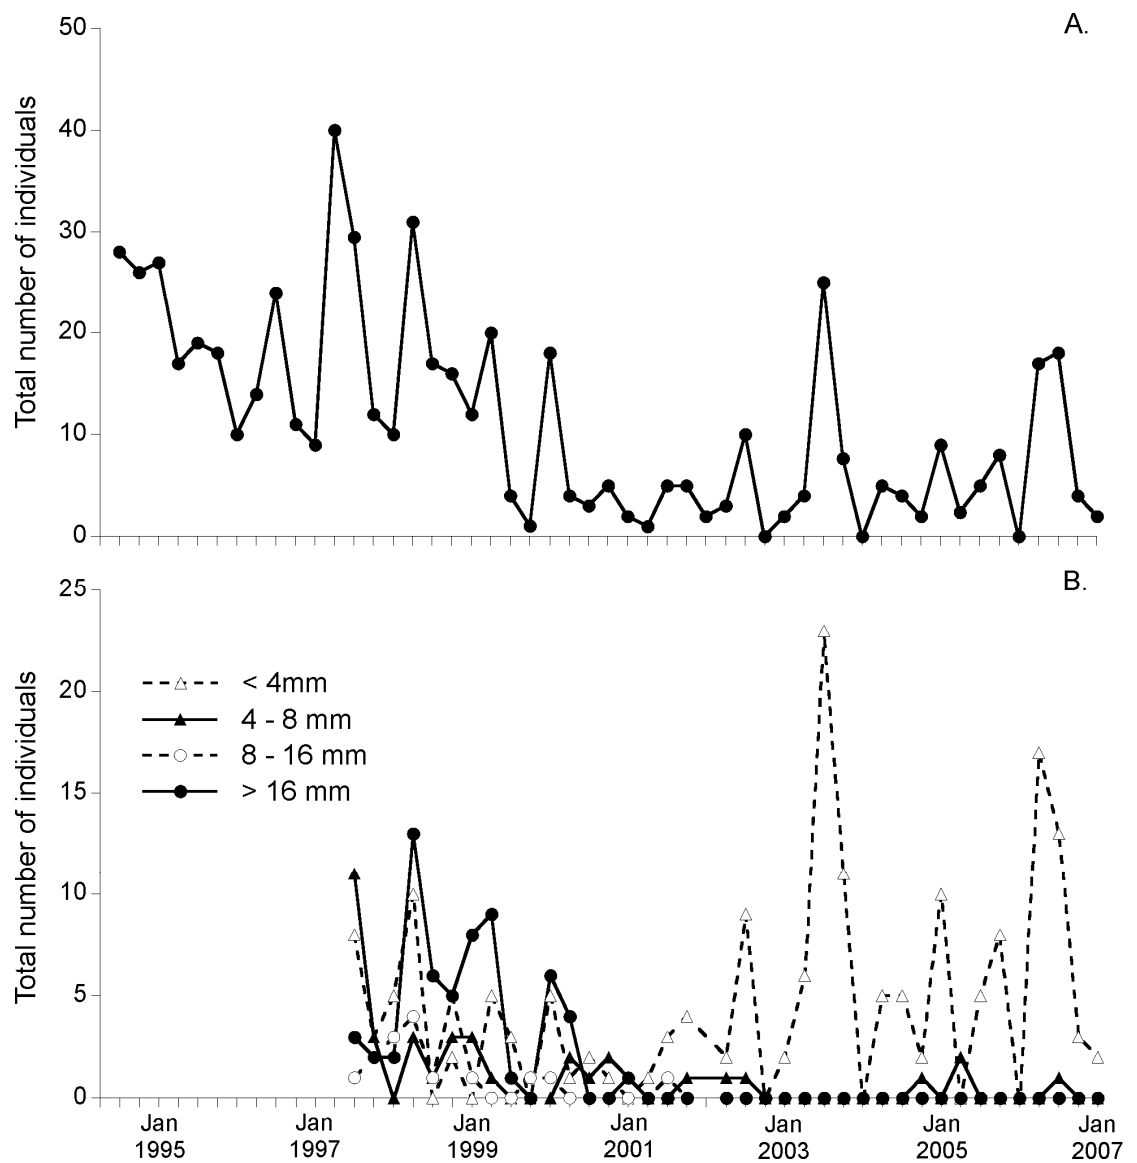

The bivalves *Austrovenus stutchburyi* and *Macomona liliana* continue to exhibit declines in abundance at Hamilton Landing. Since January 2001, between 0 and 2 individual *Austrovenus* have been found at this site. *Macomona* abundance peaks were up around its previous high values in July 2003 (25 individuals), and relatively high abundances occurred in April and July 2006 (17 and 18 individuals, respectively). Numbers of *Macomona* now appear to be steady at a new baseline abundance of 0-9 individuals (Figure 11A). The *Macomona* population at Hamilton Landing is now largely comprised of very small (<4 mm) individuals; no large, spawning sized individuals have been collected since January 2001 (Figure 11B). This indicates that juvenile *Macomona* are being supplied to this site from elsewhere in the harbour and few are surviving to adulthood.

Decreasing trends were detected for *Scoloplos cylindrifera* and *Perinereis nuntia*; these polychaetes have been scarce or absent at Hamilton Landing since July 1999.

Figure 11.

A. The total number of *Macomona liliana* collected on each sampling occasion at Hamilton Landing. A decreasing trend in overall abundance was detected for this bivalve.

B. The total number of individuals in each size class, from July 1997 onwards.

4.1.2.3 Jamieson Bay

Nucula hartvigiana was the first or second most abundant species at Jamieson Bay between April 2005 and January 2007 (Table 3), when 36-366 individuals were found. Polydorids were amongst the three dominant monitored species on five of the eight most recent sampling dates (14-260 individuals).

Heteromastus filiformis (15-85 individuals) and *Macomona liliana* (7-84 individuals) were the second or third most abundant taxa on four and three occasions, respectively. The amphipods *Paracalliope novizelandiae* (0-30 individuals) and *Torridoharpinia hurleyi* (1-27 individuals), the polychaete *Aonides oxycephala* (8-27 individuals), and oligochaetes have all featured in the dominant taxa list once over the past two years (Table 3). All of these taxa have featured amongst the dominant taxa list at this site over the course of the monitoring programme (Table 3).

Table 3.

The three dominant taxa collected at Jamieson Bay from July 1994 to January 2007. The most abundant taxa is on the left hand side of the table. When more than one taxa has the same rank they are represented as (for example) '*Arthritica bifurca* / *Cossura* sp.').

Populations showing cyclic abundance patterns

Three populations exhibit annual cyclic abundance patterns at Jamieson Bay: polydorids, *Aricidea* sp. and *Nucula hartvigiana*. Polydorids have highest numbers in July or April each year, although there was no abundance peak for this polychaete between April of 1998 and 1999 (Figure 6C). *Aricidea* peak abundances occur in either July or October months, while *Nucula* consistently exhibits its highest numbers in January or April.

The cyclic abundance patterns noted for *Heteromastus filiformis*, *Macomona liliana* and *Austrovenus stutchburyi* in our 2005 report are no longer apparent with the addition of two more years of data.

Populations showing trends in abundance

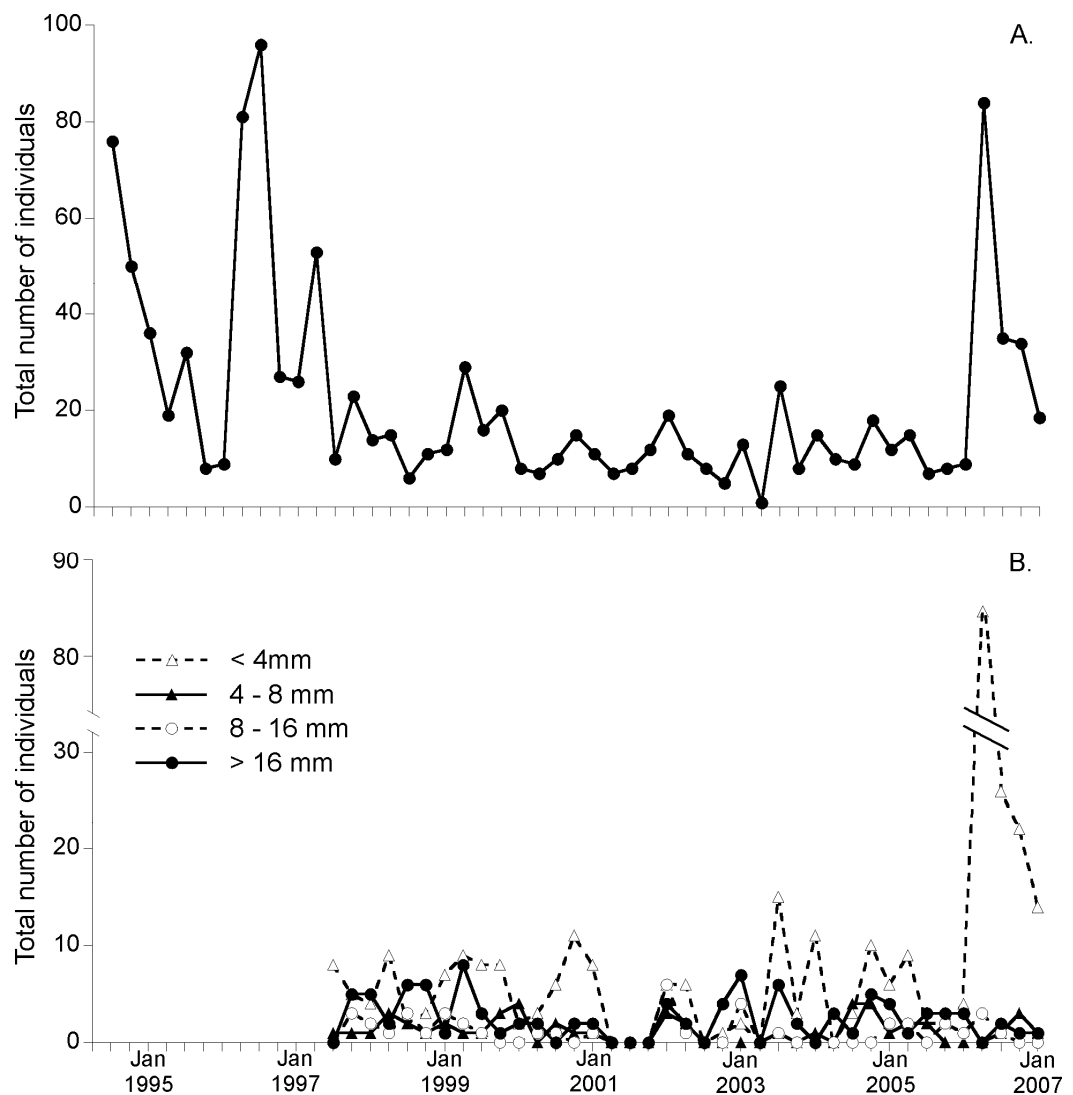

Statistically significant trends in abundance were detected for five populations at Jamieson Bay (Table 6). Declines in abundance were apparent for *Macomona liliana*, *Torridoharpinia hurleyi* and polydorids. *Macomona* was abundant at this site for the first three years of monitoring, after which abundances declined to around 10 individuals on average. While Fig. 12A suggests that this decline has been reversed (with a large peak in abundance in April 2006, this was comprised almost entirely of <4 mm individuals (Figure 12B). The decline in *Torridoharpinia* was also noted in our last report, although the magnitude of this trend is less now due to the relatively high numbers of this amphipod found in January 2004 (31 individuals). Polydorids exhibit a decreasing trend in both overall and basal abundances (Figure 6C).

Small increases in abundance of two populations were detected: *Arthritica bifurca* and *Aricidea* sp. (Table 6). *Arthritica* has exhibited large fluctuations in abundance in the last half of the monitoring programme, ranging from 0-25 individuals since April 2000 (compared to 0-9 prior to that time). *Aricidea* numbers have fluctuated considerably throughout the monitoring programme (ranging from 0-46 individuals), and the trend detected for this polychaete is not of concern.

The trends noted in our last report for *Owenia fusiformis* (a decrease) and *Paracalliope novizelandiae* (an increase) are no longer apparent with two more years of data (Table 6).

Figure 12.

A. Total number of *Macomona liliana* collected on each sampling occasion at Jamieson Bay. A decreasing trend in overall abundance of this bivalve was detected. B. The total number of individuals in each size class, from July 1997 onwards.

4.1.2.4 Mid Harbour

Nucula hartvigiana continues to dominate Mid Harbour (Table 4), with between 320 and 498 individuals collected on the last eight monitoring dates. As has been the case for the last 6 years, *Arthritica bifurca* (34-110 individuals), *Cossura* sp. (24-55 individuals) and *Heteromastus filiformis* (19-56 individuals) were the second or third most abundant of the monitored taxa (Table 4) on the last eight monitoring dates.

Populations showing cyclic abundance patterns

Heteromastus filiformis and *Macrophthalmus hirtipes* (Figure 13) exhibit peaks in abundance every year at Mid Harbour, in July or October months. *Nucula hartvigiana* numbers are highest in January or October each year (except for 2003 and 2004, when peak abundances occurred in April). *Cossura* sp. exhibits peaks annually, in July, October or April months.

Arthritica bifurca has exhibited peaks in its abundance every few years over the monitored period, but the timing of these is not predictable.

Figure 13.

Total number of *Macrophthalmus hirtipes* collected on each sampling occasion at Mid Harbour. Peaks in abundance of this crab occur annually, most often in July or October months.

Populations showing trends in abundance

Three populations exhibit trends in abundance at Mid Harbour: *Arthritica bifurca* and *Paracalliope novizelandiae* (increases) and *Notoacmea helmsi* (a decrease). An increase of *Arthritica bifurca* was also noted in our 2003 report (Table 6).

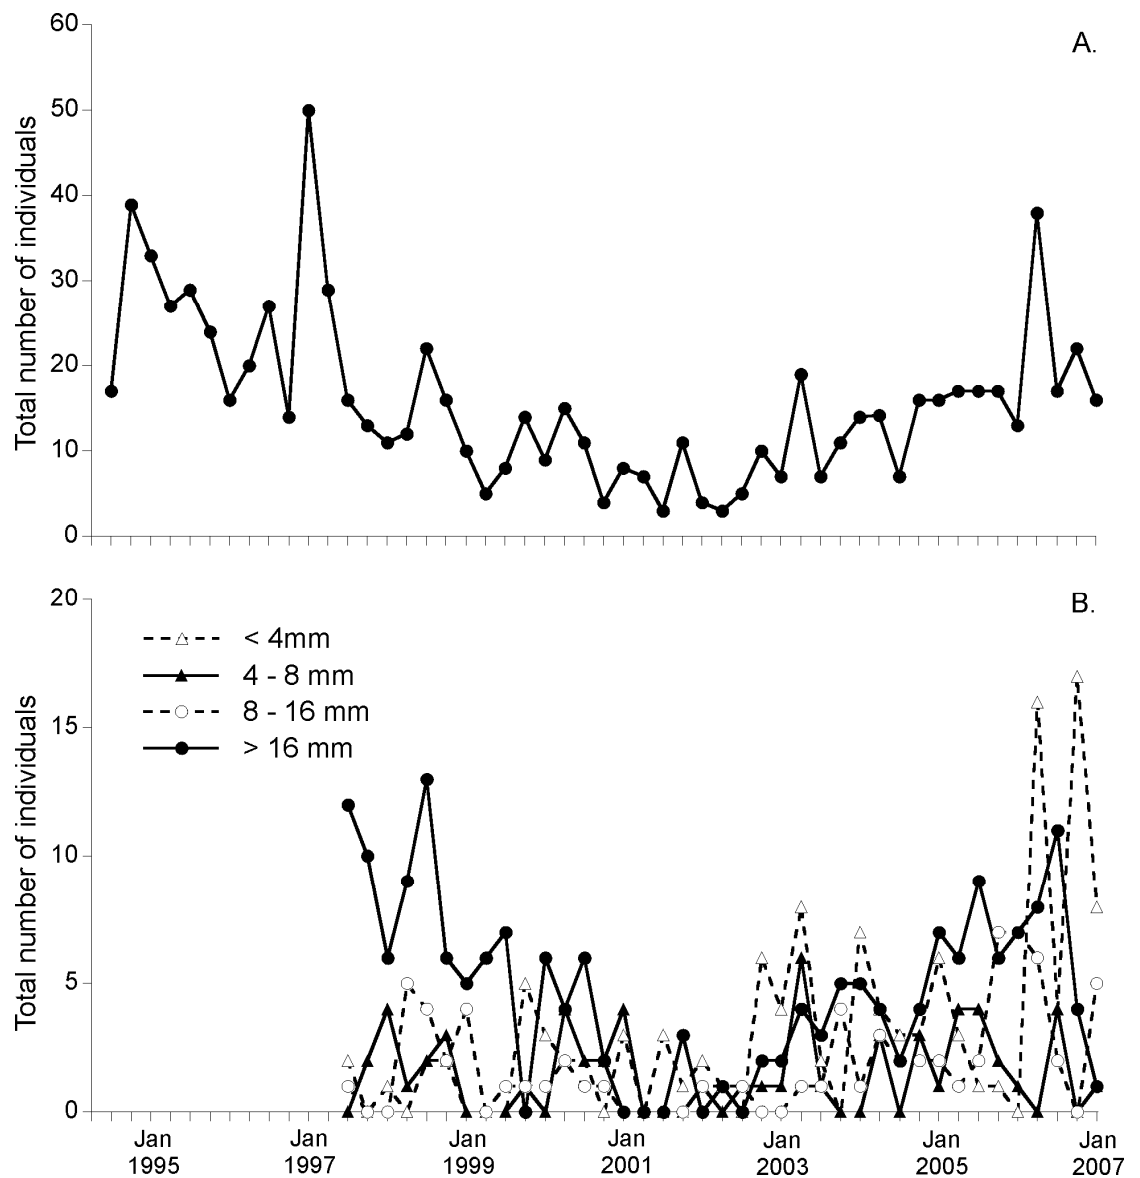

The magnitudes of the trends noted for *Paracalliope novizelandiae* and *Notoacmea helmsi* were both very small (Table 6). Considering the sporadic occurrences and low abundances of these species at this site, we do not consider these trends to be ecologically important.

The decreasing trend noted for *Macomona liliana* in our last report is no longer detectable. This bivalve exhibited a decline in numbers in the middle of the monitoring programme. Peak abundances are now similar to those noted prior to this decline, and baseline abundances have increased (Figure 14A). The population is now comprised of individuals of a range of sizes and, encouragingly, there have been two recruitment peaks in the past two years (indicated by high numbers of <4 mm individuals; Figure 14B).

The increasing trend noted for *Aricidea* sp. in our last report is no longer apparent with two more years of data (Table 6).

Figure 14.

A. Total number of *Macomona liliana* collected on each sampling occasion at Mid Harbour. The decreasing trend in abundance of this bivalve noted in previous years is no longer apparent. B. The total number of individuals in each size class, from July 1997 onwards.

4.1.2.5 Te Kapa Inlet

The Te Kapa Inlet monitored community has been dominated by three taxa over the last two years of monitoring (Table 5). *Cossura* sp., the most abundant species, has continually been found in very high numbers (304-536 individuals) since the last report. *Heteromastus filiformis* was the second most abundant taxa over this same time period, with 117-339 individuals collected. *Aricidea* sp. (55-129 individuals) was the third most abundant taxa on all but the most recent sampling date (January 2007), when *Nucula hartvigiana* (12-64 individuals) was more common. All four of these taxa have featured amongst the most dominant at this site over the course of the monitoring programme..

Populations showing cyclic abundance patterns

Only three of the eight populations that exhibited cyclic patterns in abundance at Te Kapa Inlet in 2005 still do so (i.e., *Aricidea* sp., *Heteromastus filiformis* and polydorids). The cyclic patterns noted for *Scoloplos cylindrifer*, *Macomona liliana*, *Austrovenus stutchburyi*, *Arthritica bifurca* and oligochaetes in our last report are no longer apparent with the addition of two more years of data.

Aricidea sp. and *Heteromastus filiformis* exhibit peaks in abundance each year, but the timing of these peaks is not predictable. Polydorids show a greater than annual cycle in abundance; peaks have occurred every two years since April 1998, and generally in July or October months (although the most recent occurred in April, Figure 6E).

Populations showing trends in abundance

Trends in abundance were detected for ten populations at Te Kapa Inlet: five are increasing trends and five are decreasing.

There has been a large increase in numbers of *Cossura* sp. at this site, particularly in the last half of the monitored period (abundances ranged from 1-367 prior to July 2000, and 143-810 since this time). *Heteromastus filiformis* has continued to increase since monitoring began. Small increases in abundances of nemerteans and *Scoloplos cylindrifer* were also detected. An increasing trend has been detected for nemerteans on every occasion that trend analysis has been conducted (Table 6). However, the magnitude of this trend is now smaller and numbers are more similar to those collected in the first year of monitoring, perhaps reflecting a longer term cycle in the abundance of this taxa (Figure 15). A new trend was detected for *Arthritica bifurca*; the increase in abundance of this small bivalve is likely to be due to the relatively high numbers found on two recent sampling dates and may be disproved with collection of more data.

Figure15.

Total number of nemerteans collected on each sampling occasion at Te Kapa Inlet. An increasing trend in abundance has been detected for this species.

A decline in abundance of *Austrovenus stutchburyi* was again detected at this site (Table 6), and lowest ever numbers of this bivalve were recorded on the most recent sampling occasion (i.e., 7 individuals; Figure 16A). Abundances of all size classes of *Austrovenus stutchburyi* have fluctuated over the monitoring period (Figure 16B).

Numbers of *Prionospio aucklandica* have also continued to decline at this site. A significant peak in abundance of polydorids was noted in recent months (Figure 6E), and this is reflected in the smaller magnitude of the decreasing trend noted for this taxa in this years analysis, compared to previously (Table 6).

Declines in abundance of *Nucula hartvigiana* and *Notoacmea helmsi* were also detected. In the case of *Notoacmea helmsi*, however, this trend is driven by high numbers of this limpet on the first sampling occasion (39 individuals) and this trend is unlikely to be ecologically significant.

The decreasing trends in abundance noted for *Macomona liliana* and *Torridoharpinia hurleyi* in our previous report are no longer apparent. For *Macomona liliana* this is encouraging, as it is largely due to a big peak in abundance of this bivalve (80 individuals) in April 2006 (Figure 17A). Examination of the size classes of individuals collected on this date reveals this peak was due to large numbers of <4 mm sized individuals. In fact, the population was comprised mostly of this size class on each of the four recent sampling dates (Figure 17B). This is the first influx of small bivalves of this magnitude to occur at Te Kapa Inlet since measurements began in July 1997. However, no increase in large-sized animals has yet been observed.

Figure 16.

A. Total number of *Austrovenus stutchburyi* collected on each sampling occasion at Te Kapa Inlet. A decreasing trend in overall abundance of this bivalve was detected. B. The total number of individuals in each size class, from July 1997 onwards.

Figure 17.

A. Total number of *Macomona liliana* collected on each sampling occasion at Te Kapa Inlet. The decreasing trend in overall abundance of this bivalve detected in previous years is no longer apparent. B. The total number of individuals in each size class, from July 1997 onwards.

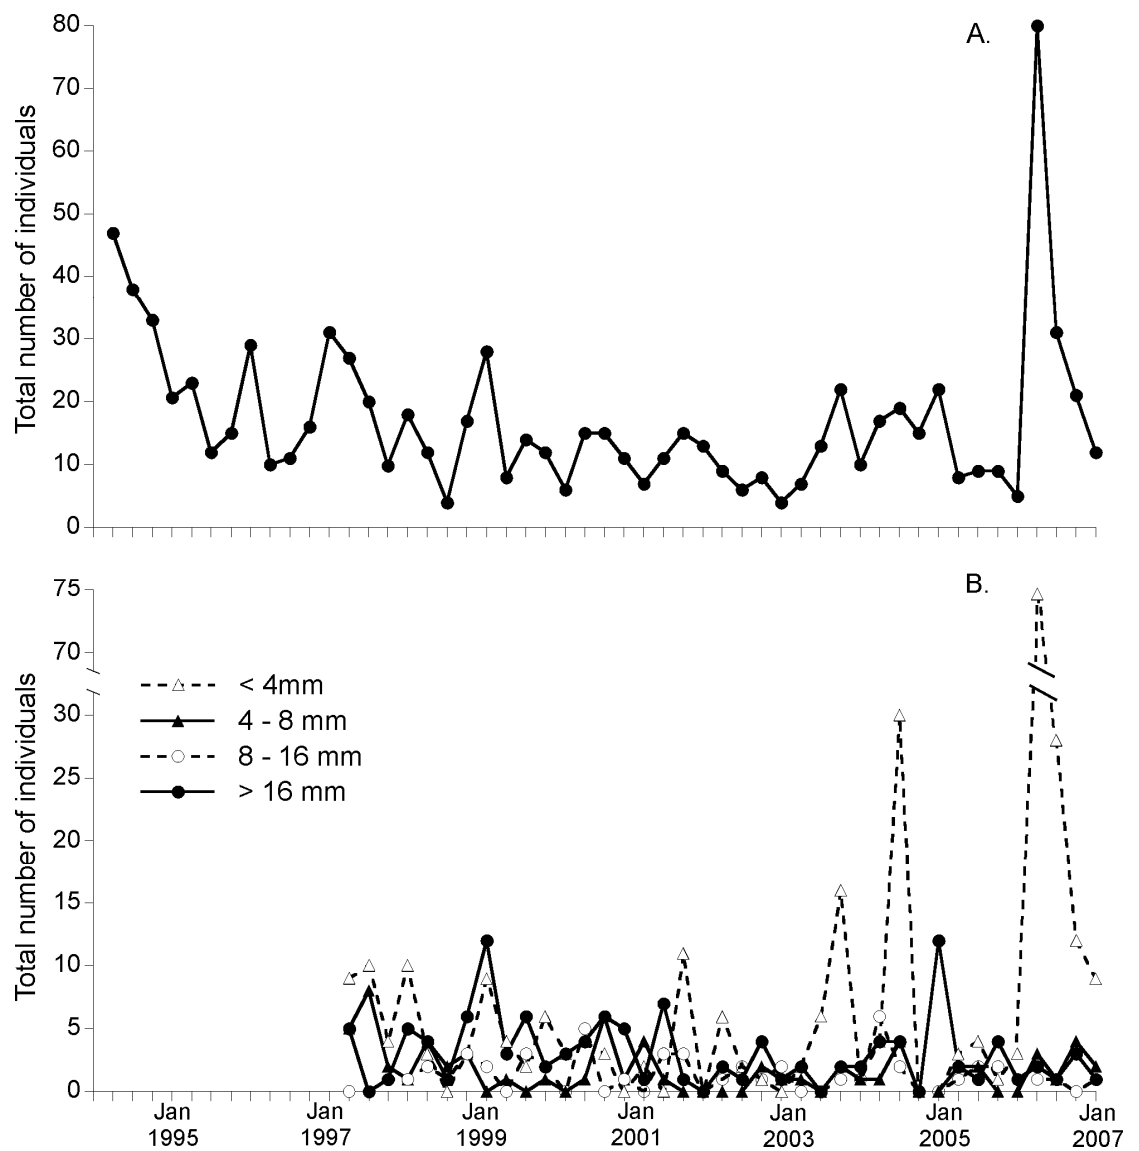

Table 6.

Trends in abundance of intertidal taxa at each site detected using regression analysis. Populations with significant trends in 2005 and/or 2007 are included. Negative numbers indicate a decrease in abundance, while positive numbers indicate an increase. Analysis of each taxa was conducted firstly on all data, and then, if a repeatable cyclic abundance pattern was apparent, on baseline data with peak abundances removed. Baseline trends are shown in parentheses. * indicates statistically significant trends that are considered unlikely to be ecologically significant due to low and/or sporadic occurrences of these taxa.

4.1.2.6 Dyers Creek

Dyers Creek is situated on the western side of Mahurangi Estuary, immediately south of Cowans Bay (Figure 1). The Dyers Creek subcatchment is one of the priority subcatchments being targeted for remedial work under the Mahurangi Action Plan (MAP). ARC initiated the MAP, in partnership with Rodney District Council and the local community, with the objective of reducing erosion and sedimentation. It includes an environmental education programme for schools, community groups and other interested members of the public. The focus has been fencing and riparian planting to reduce input of sediments into the estuary. The MAP recognised that monitoring of sites in the receiving estuary below targeted subcatchments would be useful to assess the effectiveness of these remedial actions. This monitoring may detect changes over time in the local ecology that might then be able to be linked to changes in catchment management. For this reason, a long term monitoring site was established in Dyers Creek in October 2005.

Remedial work began in the Dyers Creek subcatchment in 2006. The amount of riparian fencing in this subcatchment had been increased by 10.83% in April 2006 (MAP newsletter, April 2006), and riparian planting grants for 5000 plants have recently been awarded to residents (Megan Stewart, ARC, pers comm.).

Dyers Creek in 1993

Dyers Creek was one of 20 intertidal sites visited as part of the April 1993 survey of Mahurangi Harbour, which was conducted to identify potential sites for this long term monitoring programme (Cummings et al. 1994). Although this early survey sampling consisted of only 5 samples, collected 5 m apart, and on only one occasion, it will provide baseline information against which to determine whether the present community at this site is radically different today. The site sampled at that time (36° 28.00'S, 174° 42.90'E) was noted as being "firm mud with small mangroves" with a higher shore area comprised of

rockier substrate, and was characterised as 'a muddy site dominated by bivalves'. *Austrovenus stutchburyi*, *Prionospio aucklandica*, *Heteromastus filiformis* and *Nucula hartvigiana*, dominated the macrobenthic community at the site, and *Macomona liliana*, *Notoacmea helmsi*, *Perinereis nuntia* and cirratulids were also common (Table 7). All of these species, except cirratulids, are routinely counted as part of this monitoring programme.

Dyers Creek was one of the five intertidal areas originally recommended for establishment of a long term monitoring site as a result of the initial survey (Cummings et al. 1994). However, due to the close proximity of the oyster farms which surround this intertidal flat, and the concern that these might modify the site in some way, an alternative long term site was established in Cowans Bay (Cummings et al. 1994).

Table 7.

Taxa found in the initial survey of Dyers Creek in April 1993. Numbers are based on individuals found in 10 cm diameter cores. 'Corrected average' denotes abundances adjusted to a 13 cm diam.core, the size used in the current monitoring programme; 'Adjusted total' = 1993 abundances adjusted to the total number of individuals in twelve 13 cm diam. cores (to allow direct comparison to the numbers discussed throughout this report).

Dyers Creek October 2005-January 2007

Site description

In October 2005 a 100 × 90 m site was chosen and established by ARC. The site is comprised of muddy sand (firm underfoot) with a silty surface layer.

When established in October 2005, the site had a covering of dead shells, and contained two obvious patches of seagrass (Plate 1); the largest of which was approximately 5 × 10 m. Other patches of seagrass were noted a few hundred metres to the north of the monitoring site. The size, shape and condition of the seagrass patches has fluctuated since October 2005. For example, in July 2006 the patches appeared brown, less dense and smaller (N. Hancock, pers. obs.), but their condition had improved by the next sampling occasion (October 2006). Such changes over time are not unexpected for seagrass, and are in part a reflection of changes in light conditions and nutrient availability with season.

Mangrove seedlings have also been noted at the site on several occasions, and in April 2007 some had become established as small plants (approx. 15 cm high; N. Hancock, pers. obs.)

Occurrence of monitored taxa

Dyers Creek today is dominated by the bivalves *Nucula hartvigiana* (358-467 individuals) and *Austrovenus stutchburyi* (117-293 individuals). These were the first and second most abundant, respectively, of the monitored taxa collected from October 2005 to January 2007 (Table 8). *Heteromastus filiformis* was also common (53-119 individuals), and *Macomona liliana* has appeared amongst three dominant taxa on one occasion (57 individuals). *Macomona* is found consistently at this site, in low numbers (31-87 individuals).

Prionospio aucklandica, *Notoacmea helmsi*, *Perinereis nuntia*, all common at this site in April 1993, were found in varying abundances over the past two years (Appendix 4). *Notoacmea helmsi* was moderately abundant (total of 15-55 individuals per core), numbers of *Prionospio aucklandica* were low (1-16 inds) and *Perinereis nuntia* was rare (found only on two occasions, at a maximum of 4 individuals). *Aricidea* sp., *Arthritica bifurca* and polydorids were routinely found at this site (abundances ranged from 11-34, 11-43 and 6-43 individuals, respectively). *Scoloplos cylindrifer*, *Paracalliope novizelandiae*, *Torridoharpinia hurleyi* all reach moderate abundances on some occasions, but their numbers fluctuate (Appendix 4).

Plate 1.

Dyers Creek monitoring site in October 2005. The site is comprised of muddy sand with a covering of shells (top photo), and contained two obvious patches of seagrass (bottom photo).

Table 8.

Populations showing cyclic patterns or trends in abundance

More data are required from Dyers Creek before any trends or patterns in abundance of any of the monitored taxa can be elucidated.

4.1.3 Intertidal sites - general patterns

4.1.3.1 Harbour-wide patterns in intertidal macrofaunal populations

Populations showing cyclic abundance patterns

Only seven taxa exhibit cyclic abundance patterns (Table 9). Very few of these taxa exhibit highly predictable patterns, where peaks in abundance occur in the same monitoring month every year. Interestingly though, the taxa that do are found at the muddiest of the intertidal sites, Cowans Bay (i.e., *Nucula hartvigiana*) and Hamilton Landing (i.e., *Heteromastus filiformis*, *Macrophthalmus hirtipes* and polydorids). This could be an indication that these sites are more stable.

Table 9.

Summary of monitored taxa currently exhibiting cyclic abundance patterns at the Mahurangi intertidal monitoring sites. * peaks occur annually but month of occurrence varies; > indicates a greater than annual abundance cycle. CB = Cowans Bay, HL = Hamilton Landing, JB = Jamieson Bay, MH = Mid Harbour, TK = Te Kapa Inlet.

Taxa currently showing cyclic abundance pattern	CB	HL	JB	MH	TK

<i>Macrophthalmus hirtipes</i>	Jan/Oct	Oct	.	Jul/Oct	.
<i>Nucula hartvigiana</i>	Jan	.	Jan/Apr	Jan/Oct	.
Polydorids	.	Jan	Jul/Apr	.	Jul/Oct (>)

Populations showing trends in abundance

A total of 33 populations are currently showing trends in abundance; 17 of these are increasing trends and 16 are decreasing trends. All sites have populations that are exhibiting trends; most occur at Hamilton Landing and Te Kapa Inlet (10 populations each), and the least at Mid Harbour (3 populations). Considerably more trends were detected in this year's analysis compared with those noted in our 2005 report, (26 populations, Cummings et al. 2005). However, only 24 of these trends detected as significant in this year's analysis are considered to be ecologically significant (see Table 10).

Four species considered sensitive to increased suspended sediment concentrations are exhibiting declines in abundance in Mahurangi Estuary (Table 10). Three of the important bivalve taxa, *Macomona liliana*, *Austrovenus stutchburyi* and *Nucula hartvigiana* are declining at two sites each. The decline in abundance previously noted for *Macomona* at Hamilton Landing and Jamieson Bay is still apparent (Table 6). Despite this, there is some encouraging news with respect to trends in abundances of *Macomona* populations. With two more years of data, the decreases noted for this bivalve at Mid Harbour and Te Kapa Inlet in previous years are no longer apparent. In both cases this is in part due to a high peak in abundance of small (<4 mm) individuals in April 2006 (Figures 14 & 17). A peak in abundance of small individuals was also observed on this date at Jamesons Bay (Figure 12). These increased numbers are supported by higher numbers of larger, spawning sized individuals at Mid Harbour (Figure 14), indicating that this increase may continue in future years as these resident adults continue to reproduce. This may not persist at Te Kapa Inlet or Jamieson Bay, however, where abundances of spawning sized individuals are low (Figures 12B & 17B). This suggests that the influx of small individuals to these sites may be largely due to transport of juveniles from elsewhere in the harbour.

Austrovenus stutchburyi is exhibiting declines in abundance at Hamilton Landing and Te Kapa Inlet. In our last report we noted the disappearance of a decreasing trend at Te Kapa Inlet. In recent months, however, numbers of *Austrovenus* have been the lowest ever recorded at this site, and this trend is again apparent (Table 6). *Nucula hartvigiana* is also declining in abundance at Te Kapa Inlet, as well as at Cowans Bay. In our early monitoring reports we noted that the Te Kapa Inlet site was unusual in that the half closest to the inlet entrance had sandy substrate while the upper inlet half was muddy (Cummings et al. 1995). This muddy area has gradually expanded, and in 2003 we noted that it covered approximately $\frac{4}{5}$ of the sampling area (Cummings et al. 2003). There is now only a small portion of the north-western corner of this site which is sandy (N. Hancock, pers obs), and generally only one of the 12 replicate cores is taken from this area of the site. This change is highly correlated with the decline in abundance of *Austrovenus* at this site. However, we do note that a considerable amount of planting grants have been awarded to residents of the Te Kapa Inlet catchment as part of the MAP (i.e., 32,000 plants; Megan Stewart,

ARC, pers comm.), which may have positive implications in reducing sediment inputs to this monitoring site in future.

Scoloplos cylindrifera has declined markedly at Hamilton Landing over the monitored period. This polychaete is considered sensitive to increased suspended sediment concentrations. Prior to October 1999 between 0 and 54 individual *Scoloplos* were collected on any one sampling date, but it has since been found at this site in very low numbers (1-2 individuals) and on few occasions.

We noted in our last report that polydorid polychaetes were exhibiting decreasing trends in abundance at all of the intertidal sites except Mid Harbour. These polychaetes are still declining in abundance at three of these sites, but there is no longer a decreasing trend at Cowans Bay. These switching patterns support the idea that these polychaetes exhibit greater than annual cyclic abundance patterns (on the order of 5 to 7 years), as noted for the polydorid *Boccardia syrtis* in Manukau Harbour (Funnell et al. 2003, Cummings et al. 2005). For example, the increase in abundance at Te Kapa in recent months (Figure 6E) may be the beginning of a period of peak abundance; this will be confirmed with the collection of more data.

A number of trends were detected for species that show intermediate responses to increased suspended sediment concentrations (i.e., they prefer sediment containing some mud but not in high percentages). *Cossura* sp. and *Aricidea* sp., both polychaete species that thrive in muddy, organically enriched sediments, are exhibiting increases in abundance at Te Kapa Inlet (both taxa) and Hamilton Landing (*Cossura* only). These trends at Te Kapa Inlet are likely a reflection of the continued growth of the muddy area at this site. *Cossura* sp. is exhibiting a decline in abundance at Cowans Bay. Nemerteans (Hamilton Landing/Cowans Bay), the small bivalve *Arthritica bifurca* (Jamieson Bay/Mid Harbour/Te Kapa Inlet) and the polychaete *Heteromastus filiformis* (Te Kapa Inlet/Hamilton Landing), all exhibit increases in abundance at two intertidal sites (Table 10). The polychaete *Prionospio aucklandica* is increasing at two sites (Te Kapa Inlet and Cowans Bay) and decreasing at the muddiest site (Hamilton Landing).

Several of the monitored populations exhibiting trends in abundance appear to show an increase or decrease in numbers part way through the monitored period. In many cases these 'shifts' occurred around the same time, i.e., late 1999/early 2000 (e.g., see Figures 6C, 6D, 6E, 11A, & 15). While this could be a lagged response to the increase in muddiness of the sediments that occurred in 1997, it could also be part of larger than annual cyclic abundance patterns that are also suggested for some of these taxa (see above). We recommend a more detailed assessment of this suggested pattern in our next report, once more data have been collected.

Table 10.

Summary of monitored taxa showing trends in abundance at the Mahurangi monitoring sites, and their sediment preferences (Sed Pref). Sediment preferences are derived from Tables 5 and 6 in Gibbs & Hewitt (2004) and from Norkko et al. (2001). S = Sand preference, I = prefers some mud but not in high percentages, ? = unknown preference. dec = decreasing trend, inc = increasing trend. JB = Jamieson Bay, MH = Mid Harbour, TK = Te Kapa Inlet, CB = Cowans Bay, HL = Hamilton Landing.

4.1.3.2 Intertidal macrofaunal community composition

Figure 18 shows the relative composition of the monitored-taxa communities at each site, and the temporal change in these communities over the sampling period. The Cowans Bay community has remained very stable since monitoring began, and continues to exhibit very little temporal variation in community composition relative to the other intertidal sites. The Hamilton Landing, Te Kapa Inlet and Cowans Bay sites have become more similar in recent years, and are now situated much more closely in ordination space (e.g., see January 2007 symbols). The monitored communities at Jamieson Bay, Mid Harbour and Dyers Creek are similar to each other and, as noted for the other intertidal sites, the communities at Jamieson Bay and Mid Harbour are now more similar than when monitoring began.

Figure 18.

Correspondence analysis ordination plot, showing the temporal variation in the monitored community composition at each intertidal site over the monitored period. For each site, the positions of the community on the first (July 1994) and the most recent (January 2007) sampling occasions are highlighted. To enable identification, a white symbol is used to denote the most recent sampling date for Cowans Bay. The percentage values associated with each axis indicate the % variance explained. CB = Cowans Bay, DC = Dyers Creek, HL = Hamilton Landing, JB = Jamieson Bay, MH = Mid Harbour, TK = Te Kapa Inlet.

4.2 Subtidal sites

4.2.1 Sediment characteristics

The sediment grain size composition at both of the subtidal sites has been very consistent over the past two years of monitoring (Appendix 5). There is little medium sand at either of the sites, and around twice as much fine sand at Site A than at Site C (i.e., 66-76% cf. 27-34% over the past two years). Site C sediments have a higher silt and clay (i.e., mud) content, and more gravel/shell hash than those at Site A (see Figure 19, Appendix 5).

Figure 19.

Changes in the proportions of the mud (i.e., silt + clay; <63 µm), fine sand (62.5 – 250 µm), medium sand (250 – 500 µm) and coarse fractions (>500 µm) of the sediment at each of the subtidal sites over the monitored period. Detailed sediment grain size data, on which these graphs are based, is presented in Appendix 5.

Organic content of the sediments is low and similar at both subtidal sites, although levels tend to be slightly higher at Site C on most occasions (Figure 20A; Appendix 6). In our last report we noted that the sediment organic content had generally been higher at both sites between January 2004 and January 2005 than on previous sampling dates. While this remains true for Site C, with more data this is no longer the case at Site A (Figure 20A).

Sediment chlorophyll *a* levels are also very similar at each site, and follow similar temporal fluctuations (Figure 20B; Appendix 6). Despite this, there is no predictable relationship between high and low chlorophyll *a* levels and sampling month (season). In the past two years, both sites have exhibited their highest ever chlorophyll *a* levels (in October 2005) since these samples began to be collected (Figure 20B).

Figure 20.

A. Sediment organic content, and B. sediment chlorophyll a content, at the subtidal sites.

Site A = black symbols, Site C = white symbols.

4.2.2 *Atrina zelandica*

Numbers and sizes of *Atrina* are similar at both of the subtidal sites. Numbers have remained consistently low since our last report, with 0-2 live individuals on average found in each 0.25 m² quadrat. As noted in previous reports, patches are comprised of live and dead individuals, and the proportions of each in any one quadrat are similar at the two sites. The sizes of *Atrina* over the past two years have been similar at the two sites, and are similar to the sizes noted in our

last report; this probably reflects the fact that the growth of these populations is slowing as the individuals age and reach their maximum size (Figure 21). We have not noted beds of smaller individuals in the vicinity of the areas targeted for monitoring, indicating there has been no recent recruitment to these sites.

Figure 21.

The mean size of live *Atrina zelandica* recorded in a 0.25 m² quadrat at the two subtidal sites on each sampling occasion. Site A = black symbols, Site C = white symbols.

4.2.3 Macrofauna - comments on the abundance of common taxa

The abundances of subtidal monitored taxa collected at each site on each sampling date since the last report (i.e., from April 2005 to January 2007) are given in Appendix 7.

The following are site-by-site descriptions of the monitored macrofauna. For each site, we discuss the three most abundant taxa, populations exhibiting visually identifiable cycles in abundance, and populations for which statistically identifiable trends in abundance have been detected by trend analysis (Table 13).

4.2.3.1 Site A

Seven taxa have comprised the dominant three at Site A over the past two years of monitoring: the bivalves *Theora lubrica* (0-121 individuals) and *Arthritica bifurca* (2-16 individuals) the polychaetes *Aricidea* sp. (0-17 individuals), cirratulids (4-17 individuals) and polydorids (4-79 individuals), and the amphipods *Torridoharpinia hurleyi* (5-56 individuals) and corophidae-complex (0-12 individuals) (Table 11). In previous reports *Theora lubrica* has been the dominant taxa found at subtidal Site A. However, over the last two years, whilst it has been amongst the top three ranked taxa on all but one occasion, it has only

been the most dominant on two dates. This reflects smaller sized peaks in abundance of this bivalve noted on recent sampling dates (Figure 22).

Figure 22.

The total number of *Theora lubrica* collected on each sampling occasion at the subtidal sites. Site A = black symbols, Site C = white symbols.

Populations showing cyclic abundance patterns

Three populations exhibit greater than annual abundance cycles at Site A. The polychaete *Armandia maculata* has large peaks in April, and smaller ones in October months. *Torridoharpinia hurleyi* also shows peak abundances in April or October months. Both of these patterns were also noted in our 2005 report.

Theora lubrica generally exhibits peak abundances in April (Figure 22).

Oligochaetes exhibit a greater than annual cyclic abundance pattern; its numbers have peaked in October of 1996 and 2000, and in April of 2002, 2004 and 2006.

Table 11.

The three dominant taxa collected at subtidal Site A from October 1994 to January 2007.

The most abundant taxa are on the left hand side of the table. When more than one taxa has the same rank they are represented as (for example) '*Arthritica bifurca* / *Cossura* sp.'.

Populations showing trends in abundance

Three populations, cirratulids (Figure 23), *Arthritica bifurca* and *Aricidea* sp., exhibit trends in abundance at subtidal Site A, and all of these are increases. These trends were also noted in our last report (Table 13). The magnitude of the increasing trend for cirratulid polychaetes has declined since our last report (Table 13), and may turn out to be a longer cyclic abundance pattern (Figure 23). The increase in abundance of *Theora lubrica* noted in 2005 is now no longer apparent: this trend was being driven by higher than normal peak abundances and, as noted above, these have been smaller in recent years (Figure 22). This bivalve was not found on the most recent sampling date (Figure 22).

Figure 23.

The total number of cirratulids collected on each sampling occasion at the subtidal sites. Site A = black symbols, Site C = white symbols.

4.2.3.2 Site C

Theora lubrica was the first or second most abundant monitored taxa at Site C over the last two years, when 22-385 individuals were found. Oligochaetes and cirratulids were also common (14-56 and 10-33 individuals, respectively); both were the top ranked taxa on one occasion each, and amongst the second and third most abundant on several occasions (Table 12). Polydorid polychaetes (1-78 individuals), *Arthritica bifurca* (1-21 individuals) and *Torridoharphina hurleyi* (2-43 individuals) were the second or third most common taxa on one occasion each. These species have all featured amongst the dominant taxa at this site over the monitored period (Table 12).

Populations showing cyclic abundance patterns

Theora lubrica exhibits an annual cyclic abundance pattern at Site C, with peaks occurring in April of each year, except for 1999 (October) and 2005 (July) (Figure 22).

Two new patterns are now apparent, both of them greater than annual abundance cycles. Cirratulid peak abundances occur in April (Figure 23). Corophidae-complex amphipods have exhibited peaks in abundance roughly every two years (i.e., in October 1995, April 1998, October 2000, January 2003 and January 2005; Figure 24).

Populations showing trends in abundance

Four populations are exhibiting trends in abundance at Site C, and all of these were also detected in our 2005 analysis (Table 13). *Arthritica bifurca* is now less common at this site, its numbers have declined from 9-101 individuals in the first four years of monitoring to 0-40 since that time. *Theora lubrica* is still increasing, but this increase is in its peak abundances only; basal abundances of this bivalve remain steady (Figure 22). Cirratulid polychaetes and corophidae-complex amphipods also continue to increase (Figures 23 & 24).

Table 13.

Magnitudes of trends in abundance of subtidal taxa at each site detected using regression analysis. Negative numbers indicate a decrease in abundance, while positive numbers indicate an increase.

Monitored taxa	2007	2005	2003	2001
Site A				
<i>Arthritica bifurca</i>	0.29	0.40	No trend	No trend

Subtidal sites - general patterns

4.2.3.3 Harbour-wide patterns in subtidal macrofaunal populations

Populations showing cyclic abundance patterns

Six of the monitored taxa populations exhibit cyclic patterns in abundance at the subtidal sites (Table 14).

Table 14.

Summary of monitored taxa currently exhibiting cyclic abundance patterns at the Mahurangi subtidal monitoring sites. > indicates a greater than annual abundance cycle.

Taxa currently showing cyclic abundance pattern	Site A	Site C
<i>Armandia maculata</i>	Apr/Oct	
Cirratulids	.	Apr (>)
Corophidae-complex	.	Oct/Apr/Jan (>)
Oligochaetes	Apr/Oct (>)	.
<i>Theora lubrica</i>	Apr	Apr
<i>Torridoharpinia hurleyi</i>	Apr/Oct	.

Populations showing trends in abundance

A total of seven subtidal populations and five different taxa are exhibiting trends in abundance at the Mahurangi Harbour subtidal sites (Table 15). Two taxa show trends at both sites: the bivalve *Arthritica bifurca* is increasing at Site A and decreasing at Site C, and cirratulid polychaetes are increasing in abundance at both sites. *Aricidea* sp. is increasing in abundance at Site A only, and both *Theora lubrica* and corophidae-complex amphipods are increasing at Site C. All of these taxa except corophidae-complex amphipods (for which there is no information) are known to prefer some mud content in the sediment but not high proportions (Gibbs & Hewitt 2004).

<i>Arthritica bifurca</i>	inc	dec
Cirratulids	inc	inc
Corophidae-complex	.	inc
<i>Theora lubrica</i>	.	inc

4.2.3.4 Subtidal macrofaunal community composition

As noted in our last report, while the monitored communities at Sites A and C have exhibited considerable fluctuations over the monitored period, they are currently very similar both to one another, and to the communities observed at the start of the monitoring programme (Figure 25).

Figure 25.

Correspondence analysis ordination plot, showing the temporal variation in the monitored community composition at the subtidal sites over the monitored period. For each site, the positions of the community on the first (July 1994) and the most recent (January 2007) sampling occasions are highlighted. The percentage values associated with each axis indicate the % variance explained.

5 Summary & conclusions

Sediment characteristics and populations and communities of the monitored macrofaunal taxa have not changed markedly at the intertidal or subtidal sites over the past two years of monitoring. The monitored macrofaunal communities at Hamilton Landing, Te Kapa Inlet and Cowans Bay have continued to become more similar to each other, as have those of Jamieson Bay and Mid Harbour (Figure 18). The communities at subtidal Sites A and C are also currently very similar (Figure 25).

A total of 33 intertidal populations are currently showing trends in abundance; approximately half of these are increasing trends and half are decreasing trends. All sites have populations that are exhibiting ecologically significant trends; most occur at Hamilton Landing and Te Kapa Inlet (9 and 7 populations each, respectively), and the least at Mid Harbour (1 population). Several of the monitored populations exhibiting trends in abundance appear to show an increase or decrease in numbers part way through the monitored period (i.e., late 1999/early 2000) which may be a lagged response to the increases in muddiness of the sediments that occurred throughout the estuary in 1997.

Of most concern is that four taxa considered sensitive to increased suspended sediment concentrations are exhibiting declines in abundance at the intertidal sites (Table 10). Two ecologically important bivalve species, *Macomona liliana* and *Austrovenus stutchburyi*, and the polychaete *Scoloplos cylindriger* continue to decline in abundance at the muddiest site, Hamilton Landing. *Macomona* is also declining at Jamieson Bay. Decreasing trends were detected for *Austrovenus* and the nut shell, *Nucula hartvigiana*, at Te Kapa Inlet. These declines are likely to be correlated with the continued expansion of the muddy portion of the Te Kapa Inlet site noted over the monitored period.

Despite this, there is some encouraging news with respect to trends in abundances of *Macomona* populations. The decreases noted at Mid Harbour and Te Kapa Inlet in previous years are no longer apparent with two more years of data, due in part to a high peak in abundance of small (<4 mm) individuals in April 2006 (Figures 14 & 17). Mid Harbour contains reasonable numbers of spawning sized individuals (Figure 14), indicating that this increase may continue in future years as these resident adults continue to reproduce. Abundances of spawning sized individuals are low at Te Kapa Inlet however (Figure 17), and recruitment at this site relies on transport of juveniles from elsewhere in the harbour.

Very few of the intertidal populations exhibit highly predictable cyclic abundance patterns, where peaks in abundance occur in the same monitoring month every year (Table 9). Interestingly, the taxa that do are found at the muddiest of the intertidal sites, Cowans Bay and Hamilton Landing, perhaps reflecting that these sites are relatively stable in terms of sedimentary conditions and populations (e.g., Figure 18).

Numbers and sizes of the horse mussel *Atrina zealandica* are similar at both of the subtidal sites. Numbers are low, with 0-2 live individuals on average found in a 0.25 m² quadrat on any one sampling date. The sizes of *Atrina* have not increased much over the past two years. This probably reflects the fact that the growth of these populations is slowing as the individuals age and reach their maximum size (Figure 21).

Seven subtidal populations are exhibiting trends in abundance, and all but one of these are increasing (Table 15). All of these taxa except corophidae-complex amphipods (for which there is no information) are known to prefer some mud but not high percentages (Gibbs & Hewitt 2004). Two taxa show trends at both sites: cirratulid polychaetes (increasing at both sites) and the bivalve *Arthritica bifurca* (increasing at Site A, decreasing at Site C). Six of the monitored populations exhibit cyclic patterns in abundance at the subtidal sites (Table 14).

The Dyers Creek and Te Kapa Inlet subcatchments are both being targeted for remedial work under the Mahurangi Action Plan. An additional intertidal monitoring site was established Dyers Creek in October 2005 in response to this, in order that any changes over time in its ecology may be able to be linked to these changes in catchment management. The site is comprised of muddy sand (firm underfoot) with a silty surface layer, and has a monitored community similar to that of Jamieson Bay and Mid Harbour (Figure 18). The dominant taxa include the bivalves *Nucula hartvigiana*, *Austrovenus stutchburyi* and *Macomona liliiana* and the polychaete *Heteromastus filiformis*. Comments on trends and patterns in abundance of the monitored populations and community at Dyers Creek will be made in future reports, following collection of more data.

Fluctuations in abundance of invertebrate populations is to be expected, and we must document and understand this natural variability to enable identification of 'unusual' increases or a decreases that may be due to some environmental stressor (e.g., sedimentation). Similarly, this baseline information is also needed to be able to document recovery of impacted populations. In addition, populations that are under stress tend to exhibit more variability in their abundance, so we might not expect to see a simple linear response in all populations. Some of the taxa monitored in Mahurangi Estuary are also monitored in the long term ecological monitoring programmes in Manukau and Waitemata Harbours; interpretations of trends and patterns in abundance of Mahurangi populations is done with knowledge of information on populations from Manukau in particular, where there is no sedimentation issue.

This monitoring programme has continued to provide very useful information on trends and cycles in monitored taxa populations and sediment characteristics that can be used to guide and monitor the effectiveness of catchment management within Mahurangi Estuary. With two more years of data our previous recommendations concerning the need to investigate and implement improved sediment controls still apply, as we are still detecting declines in abundance of taxa known to be sensitive to increased sediment loading. Recent evidence of recruitment of juvenile bivalves to some of the intertidal populations is encouraging, as this highlights the potential for the recovery of some areas of the harbour should these control measures be effective.

6 Acknowledgements

Thank you to Nicole Hancock for conducting the field sampling for this project over the past two years. Greig Funnell, Luca Chiaroni, Drew Lohrer, Scott Edhouse (NIWA) and Auckland Regional Council staff also helped with the field sampling. Mike Townsend (NIWA) conducted the statistical analysis.

8.3 Appendix 3

A. Organic content (% dry weight), and B. Chlorophyll a content ($\mu\text{g g}^{-1}$ sediment) of sediments at the intertidal sites on each sampling occasion since July 2000. * = highest recorded value at a particular site.

A. Organic content

8.4 Appendix 4

Summary of temporal results² at the intertidal sites from April 2005 (Time = 44) to January 2007 (Time = 51). CB = Cowans Bay, DC = Dyers Creek, HL = Hamilton Landing, JB = Jamieson Bay, MH = Mid Harbour, TK = Te Kapa Inlet.

² Data is only given if the taxa occurred at a site during this time period.

³ Total number of individuals collected in 12 samples. Calculated by mean abundance*12.

⁴ Range = between the 5th and 95th percentile.
